How ventilation can influence your classification in Ex areas?

A ventilation is defined by its availability and its degree. A good ventilation can prevent or lower the probability of the presence of a hazardous explosive atmosphere. This newsletter describes how a ventilation can influence the ATEX zoning according IEC 60079-10-1.

Artificial ventilation

With the use of artificial ventilation it is possible to achieve:

- reduction in the type and/or extent of zones
- shortening of the time of persistence of an explosive gas atmosphere
- prevention of the generation of an explosive gas atmosphere

Obstacles, turbulence and circulating air patterns may cause reduced or even no ventilation in certain parts of the area. Special attention should be paid on this phenomena.

Degree and availability of ventilation

The effectiveness of the ventilation in controlling dispersion will depend upon the degree and availability of ventilation:

- **High ventilation** can reduce the concentration at the source of release virtually instantaneously, resulting in a concentration below the lower explosive limit.
- **Medium ventilation** can control the concentration, resulting in a stable zone boundary.
- **Low ventilation** cannot control the concentration and cannot prevent a flammable atmosphere after release has stopped.

### Estimation of hypothetical volume $V_z$

If the volume $V_z$ is smaller than 0.1 m$^3$ and/or 1% of the volume served by the actual ventilation ($V_0$), the ventilation can be considered as high. If the volume $V_z$ is bigger than $V_0$, the ventilation can be considered as low.

To estimate the presence of a potential explosive atmosphere with regards to ventilation, a hypothetical volume $V_z$ is calculated:

$$V_z = \frac{(dG/dt)_{\text{max}}}{k} \cdot f \cdot \frac{T}{293} \cdot \frac{1}{C}$$

Where

- $(dG/dt)_{\text{max}}$ the maximum rate of release at source in kg/s
- $LEL_m$ lower explosive limit in kg/m$^3$
- $k$ typically $k = 0.25$ for continuous and primary grades and $0.5$ for secondary grade
- $T$ ambient temperature (in Kelvin, K)
- $C$ is the number of fresh air changes per unit time (s$^{-1}$)
- $f$ is the efficiency of the ventilation in terms of its effectiveness in diluting the explosive gas atmosphere, ranging from 1 (ideal situation) to $f = 5$ (impeded air flow).

The effect of ventilation on the type of the zones can be summarized in Table 1.

<table>
